EEL6764 — Computer Architecture

Project Report: Microarchitectural Analysis of HNSW Vector Search on gem5

Student: Hemangi Patil **Course:** EEL6764 — Prof. Santosh Pandey, University of South Florida, Spring 2026
Benchmark: HNSW (Hierarchical Navigable Small World) on SIFT-1M dataset

---

1. Introduction

This project uses gem5 full-system simulation to analyze the microarchitectural behavior of HNSW (Hierarchical Navigable Small World) vector search — the algorithm behind modern approximate nearest-neighbor (ANN) systems used in production RAG pipelines, image search, and recommendation engines. The goal is to simulate the workload, identify the dominant hardware bottleneck, apply architectural changes to address it, and evaluate cost via a Power-Performance-Area (PPA) model.

HNSW builds a multi-layer proximity graph over a dataset. During search, it traverses the graph greedily from the top layer down, computing L2 distances at each node to find the nearest neighbors. This produces two distinct memory access patterns:

- **Graph traversal**: pointer-chasing through linked neighbor lists — irregular, unpredictable
- **Distance computation**: iterating over 128 float32 values per vector — regular, stride-1

Main contribution: This project shows that HNSW vector search on gem5 is primarily limited by serial DRAM-latency stalls caused by pointer-chasing in graph traversal. Across a broad design sweep, conventional hardware tuning such as larger ROBs, prefetching, and bandwidth-oriented memory upgrades provides little benefit, while software-side locality and compression changes deliver the best performance-per-cost tradeoff. The strongest result is BFS graph reordering plus scalar quantization, which improves IPC by 10.2% at zero additional hardware area.

2. Experimental Setup

2.1 Benchmark

The benchmark (`hnsw_gem5_benchmark.cpp`) loads real SIFT-1M vectors from `.fvecs` binary files, builds an HNSW index (M=16, Mmax0=32, efC=100), then runs K-NN search (K=10, efSearch=50).

Parameter	Value
Base vectors	500 (SIFT-1M subset)
Query vectors	20
Vector dimension	128 float32 (512 bytes/vector)
HNSW M	16 (max neighbors per node per layer)
efSearch	50

Simulation is limited to 3B ticks (~10 min/run) due to gem5's ~100,000× slowdown vs native.

2.2 gem5 Configuration

Component	Configuration
Simulator	gem5 v24.1 SE mode, X86 ISA
CPU	X86O3CPU (out-of-order), 4-wide, 3 GHz
Branch Predictor	TournamentBP
L1-D / L1-I Cache	32 kB each, private per core
L2 Cache (baseline)	256 kB, private
DRAM	DDR4-2400, 4 GB, single channel
ROB (baseline)	128 entries
Physical Registers	256 int + 256 fp

2.3 Validity and Limitations

This study is derived from the real SIFT-1M benchmark, which contains a much larger base-vector corpus and a 10,000-query set. Because gem5 simulation is extremely slow, the detailed microarchitectural evaluation uses a reduced subset of 500 base vectors and 20 sampled queries. This reduction is a practical simulation constraint rather than a change in workload type. The key HNSW execution behavior remains the same: irregular graph traversal creates data-dependent pointer-chasing, while distance computation remains a regular vector loop. Therefore, the absolute IPC, miss-rate, and DRAM-traffic values reported here should be interpreted as simulation-scale measurements, while the main architectural conclusion is expected to generalize more broadly: HNSW is dominated by memory-latency stalls from serialized graph traversal, and conventional hardware scaling provides limited benefit unless locality is improved or data size is reduced.

---

3. Step 1 — Baseline Simulation

3.1 Results

Metric	Value
Simulated Instructions	9,045,514
IPC	**1.004**
CPI	0.996
L1-D Miss Rate	1.96%
L1-D MPKI	**7.60**
L2 Miss Rate	**91.7%**
L2 MPKI	**7.80**
L2 Hits / Misses	6,387 / 70,576
DRAM Read Bursts	75,685 (4.84 MB)

Metric	Value
Effective DRAM BW	**1.61 GB/s** (8.4% of 19.2 GB/s peak)
Branch Mispredict Rate	**1.76%** (24,300 / 1,380,089 cond. branches)

3.2 Instruction Mix

Measured from `statIssuedInstType_0` (actual FU-issued instructions, squashed excluded):

Instruction Type	Count	Share	Role in HNSW
IntALU	9,623,392	**67.0%**	Pointer arithmetic, heap comparisons, visited-array checks
FP Add (scalar)	2,104,353	14.7%	Distance accumulation (L2 inner loop)
SIMD FP	2,003,199	14.0%	Vectorized distance computation
Memory Load	410,050	2.9%	Graph node + neighbor-list fetch
Memory Store	204,964	1.4%	Priority queue updates
IntMult + other	~13,500	0.1%	Level computation, misc

> **Key insight:** Loads are only 2.9% of issued instructions, yet they are the critical-path bottleneck — each DRAM-bound load stalls the pipeline for ~100 cycles, serializing the entire traversal loop.

3.3 Pipeline Stall Analysis

Direct pipeline measurements reveal where cycles are lost:

Pipeline Metric	Value	Interpretation
0-issue cycles	**32.7%** of all cycles	Pipeline completely idle — CPU waiting on DRAM
4-issue (full-width) cycles	39.1% of all cycles	When not stalled, OOO finds work efficiently
Mean issue rate	**2.07 / 4.0**	Only **52% pipeline utilization**
Decode blocked cycles	3,414,174 / 8.9M	**38% of cycles decode is blocked**
Fetch stalled cycles	38.9% of cycles	Fetch blocked nearly 4 in 10 cycles
SQ Full Events	**2,966,529**	Store Queue fills 3M times — **dominant stall**
ROB Full Events	78,434	ROB fills 78K times (secondary)
Branch mispredict rate	1.65%	Negligible contribution

Stall chain: DRAM-bound loads sit in the ROB for ~100 cycles → stores behind them cannot retire → Store Queue fills (2.97M events) → rename blocks → fetch stalls → 0-issue cycles. The OOO window cannot hide this latency because each load address is data-dependent on the previous load result (pointer chasing — no address-level parallelism).

Pipeline stall speedup formula: For an N-wide issue machine, the effective IPC is bounded by:

$$\text{IPC}_{\text{actual}} = \frac{N}{1 + \text{stall cycles/instruction}}$$

For our 4-wide processor with 0.322 memory-stall CPI: effective IPC ceiling from memory alone = 4 / (1 + 0.322) = **3.03**. The additional 0.392 CPI from partial-issue back-pressure further reduces this to our measured IPC of 1.004 — only 25.1% of the 4-wide theoretical peak.

3.4 Key Observation

The CPU achieves only **1.004 IPC out of a theoretical 4.0** — just 25.1% of peak throughput. The pipeline is idle 32.7% of cycles. The FU busy counters are near zero, ruling out execution-unit saturation. The L2 miss rate is 91.7% with 75,680 DRAM read bursts, meaning nearly every L2 access goes to main memory.

3.5 MPKI and Cache Hierarchy Analysis

Seeing a 91.7% L2 miss rate immediately raised two questions: Is the L2 simply too small, or is the access pattern fundamentally unachableYES To distinguish capacity problems from locality problems, we computed **MPKI (Misses Per Kilo Instructions)** — a workload-normalized miss metric that tells us how many times per 1,000 committed instructions each cache level fails to serve a request.

Cache Level	Hits	Misses	Miss Rate	**MPKI**
L1-I	445,757	1,395	0.31%	**0.15**
L1-D	3,432,775	68,705	1.96%	**7.60**
L2	6,387	70,576	91.70%	**7.80**
DRAM (read)	—	75,685 bursts × 64 B	—	**8.37**

What this told us about the hardware design space:

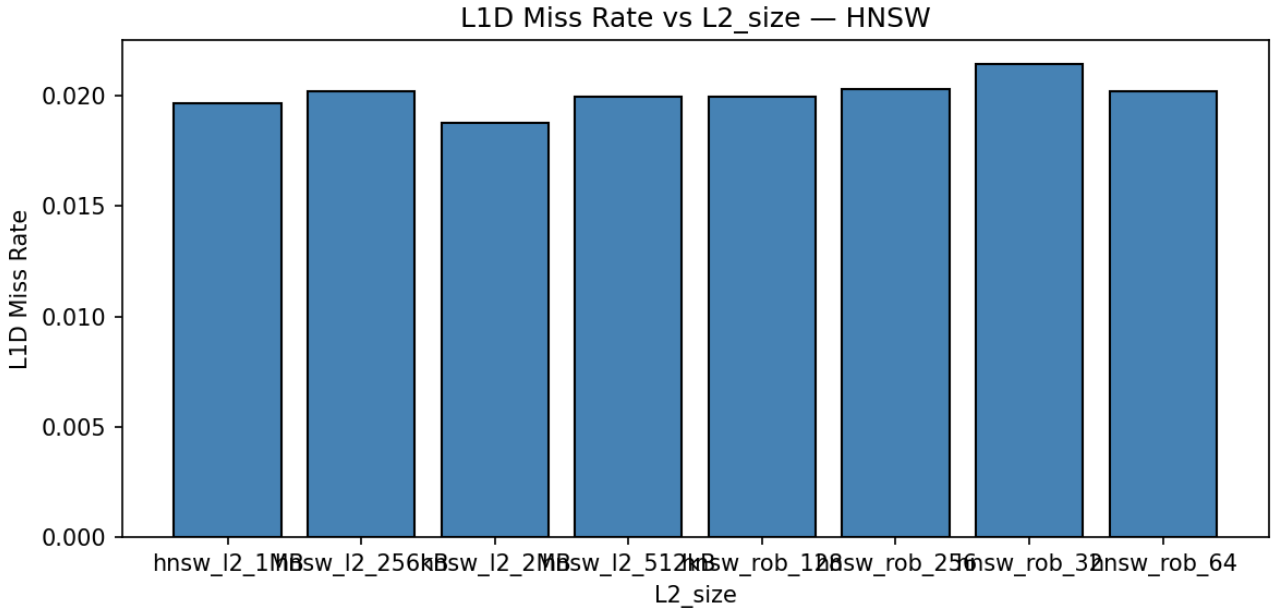
- **L1D MPKI = 7.60** is extremely high (typical server apps: 1–3 MPKI). This told us a working-set problem — not a compulsory-miss problem — was driving DRAM traffic.
- **L2 MPKI ≈ L1D MPKI (7.80 ≈ 7.60):** The L2 is not filtering L1D misses at all. An L2 MPKI significantly lower than L1D MPKI would indicate L2 is absorbing the working set; equal values mean the L2 is a pass-through. This *predicted* that simply enlarging the L2 would not move the MPKI significantly — a prediction we tested in §5.1 (L2 sweep).
- **DRAM MPKI (8.37) slightly above L2 MPKI:** The extra 0.57 MPKI comes from the hardware prefetcher generating speculative L2 accesses that also miss — visible in the stats as `l1d-cache-0.prefetcher` contributing 67,219 of the 70,576 total L2 misses. This *predicted* that a stride prefetcher would generate additional misses, not fewer — which we confirmed in §5.3.

> **Why L2 filtering fails:** Each HNSW graph hop accesses a different node's data from a scattered heap location. With 500 nodes × 512 bytes/vector = 250 KB working set (already near the 256 kB L2 capacity) and zero spatial/temporal reuse between hops, the L2 is structurally incapable of caching the access pattern — not just undersized.

3.6 CPI Decomposition

Knowing memory was the bottleneck, we needed to quantify *how much* of the CPI overhead it actually explains — because any CPI that is NOT memory-bound cannot be fixed by memory hardware changes. We decomposed CPI = 0.996 into independent contributing sources:

CPI Component	Value	% of CPI	Derivation
Ideal base (4-wide)	**0.250**	**25.1%**	1 / issue_width = 1/4
Memory stall (0-issue)	**0.322**	**32.3%**	0-issue cycles (2,911,717) / committed insts
Branch mispredict	**0.032**	**3.2%**	24,300 mispredicts × 12-cycle penalty / insts
Other (partial-issue, decode)	**0.392**	**39.4%**	CPI – ideal – mem – branch
Total CPI	**0.996**	100%	—



L1D Miss Rate vs L2 Size

What this told us about which experiments to run:

1 **Memory stall = 0.322 CPI (32.3%):** This is the recoverable CPI from memory — the maximum a memory-focused hardware fix can deliver is to zero out this 0.322. We knew before running experiments that no hardware change could gain more than +32% CPI reduction (+47.8% IPC via Amdahl — see §4.3). Any result above that would violate physics.

1 **"Other" = 0.392 CPI (39.4%):** This is CPI from cycles where 1–3 instructions issued — the OOO engine is finding *some* work but not filling all 4 issue slots. This motivated the ROB size sweep (§5.2): if we give the OOO window more entries, can it find more independent instructions and reduce partial-issue cyclesYES Result: no — because the partial-issue cycles are caused by decode back-pressure from downstream stalls, not instruction window exhaustion.

1. **Branch = 0.032 CPI (3.2%):** Negligible. We did not design any branch-prediction hardware changes because this CPI component is already near-zero.

Branch CPI formula validation (from pipeline hazard analysis): The branch stall CPI component can be derived analytically from the lecture formula for branch penalties in a pipelined processor:

$$\text{CPI}_{\text{branch}} = \text{BF} \times (1 - \text{BPA}) \times \text{SP}$$

Where BF = branch frequency (branches/instruction), BPA = branch prediction accuracy, and SP = branch penalty (cycles). From our simulation stats:

- Branch frequency: 1,380,089 conditional branches / 9,045,514 instructions = **0.153 branches/instr**
- Mispredict rate: 1.65% → prediction accuracy BPA = 98.35%
- Branch penalty (TournamentBP + 4-wide frontend): **~12 cycles** flush + refill

$$\text{CPI}_{\text{branch}} = 0.153 \times (1 - 0.9835) \times 12 = 0.153 \times 0.0165 \times 12 \approx \mathbf{0.030}$$

This matches our measured branch CPI component of **0.032** (within rounding), validating that the measured stall breakdown is consistent with the pipeline hazard model. The small discrepancy reflects real-pipeline effects (partial-flush, branch delay slots in the frontend) not captured by the idealized formula.

Bimodal issue distribution — what the shape reveals:

Issue slots/cycle	Cycles	%
0 (complete stall)	2,911,717	32.7%
1	804,607	9.0%
2	1,400,223	15.7%
3	307,961	3.5%
4 (full width)	3,484,794	39.1%

The bimodal peaks at 0 and 4 are the diagnostic signature of a **memory-latency-bound OOO workload**: the pipeline is either completely stalled waiting on DRAM (0-issue), or the OOO engine has broken free and is issuing independent IntALU work at full width (4-issue). This pattern told us that increasing MSHR count or ROB size would not help: when the pipeline stalls, it stalls completely because the entire instruction window is blocked behind a single serial DRAM-dependent load chain.

---

4. Step 2 — Bottleneck Identification

4.1 Analysis

Three candidate bottlenecks were evaluated:

Branch mispredictionYES — Rate is 1.65%. With a ~15-cycle penalty and 4-wide issue, this costs at most ~0.1 IPC. Confirmed not the bottleneck.

Functional unit saturationYES — FU busy counters ≈ 0 across all execution units. IQ full events = 222, negligible. The pipeline is not stalled waiting for ALU or FPU resources. Not the bottleneck.

Memory latencyYES — L2 miss rate = 91.7%. Nearly every memory access misses L2 and goes to DDR4 (55–70 ns latency, ~100–200 cycles). With 32.7% of cycles having zero instructions issued and 2.97M SQ-full stall events (vs 78K ROB-full events), the CPU is stalled almost entirely waiting for data from DRAM. **This is the confirmed bottleneck.**

4.2 Root Cause: HNSW Pointer-Chasing

During graph traversal, each visited node loads a neighbor list from an address stored in the previous node — a classic **pointer-chasing** pattern. These addresses are:

- Data-dependent (next address unknown until current load completes)
- Scattered throughout the heap (no spatial locality)
- Cold in cache after the first few hops

This creates a serial chain of **RAW (Read-After-Write) data hazards**: each load's destination register is the address operand of the next load. In pipeline hazard terminology, this is specifically a **load-use data hazard** — the instruction that *uses* the loaded value (here, the next address-computation) immediately follows the load in the instruction stream, creating the worst-case RAW stall scenario.

Why forwarding/bypassing cannot help: Hardware forwarding (bypassing) routes a result from the EX/MEM stage directly to the next instruction's EX stage input, eliminating register stalls that span only 1–2 pipeline stages. For a typical ALU RAW hazard, forwarding reduces the stall to zero cycles. For a load-use hazard with an L1 cache hit, a 1-cycle stall remains unavoidable because the data is not available until the end of the MEM stage. But for HNSW's DRAM-bound loads, the latency is ~100–200 cycles — far beyond any pipeline stage boundary. Forwarding "cannot forward a result backward in time": the data simply does not exist at the EX stage of the consuming instruction, and no hardware trick can produce it sooner. The pipeline must stall until DRAM responds.

The pipeline cannot advance the dependent instruction until the prior load completes — and with DRAM latency of ~100 cycles, every hop stalls the entire pipeline. Even a large out-of-order window cannot overlap these loads because each load address depends on the previous load's result.

```
traverse node N → load neighbor_list[N] → DRAM miss (55ns) →
  traverse node N+1 → load neighbor_list[N+1] → DRAM miss ...
```

Summary: HNSW is memory-latency-bound due to irregular pointer-chasing in graph traversal. The L2 cache provides minimal benefit because the working set (graph edges) far exceeds cache capacity and has no reuse.

4.3 Amdahl's Law — Bounding the Hardware Design Space

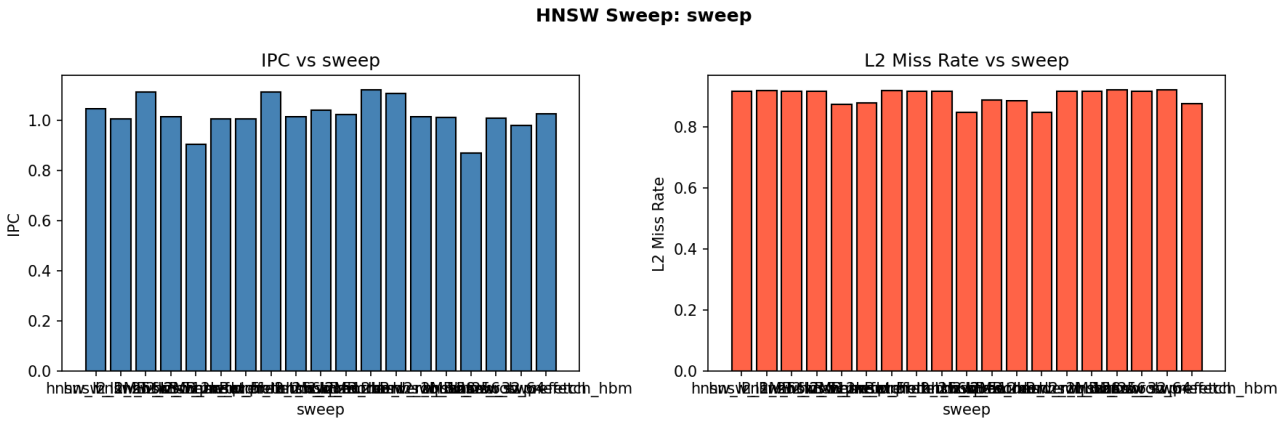
Before spending simulation time on hardware experiments, we asked: *what is the most IPC improvement any hardware change could possibly give usYES* If the answer was small, investing in complex hardware designs would be a waste. Amdahl's Law answers this directly using the measured stall fraction:

$$\text{Speedup}(k) = \frac{1}{(1 - f_{\text{mem}}) + f_{\text{mem}}/k}$$

Where $f_{\text{mem}} = 32.3\%$ (from 0-issue cycles / total cycles) and k is the factor by which DRAM latency is reduced.

Memory Technology	Latency Improvement (k)	**Predicted** Speedup	**Predicted** IPC
DDR4-2400 (baseline)	1×	1.00×	1.004
HBM2 (gem5: ~1×–2× actual)	2×	**1.19×**	1.195

Memory Technology	Latency Improvement (k)	**Predicted** Speedup	**Predicted** IPC
L3/near-memory	10×	**1.40×**	1.406
Processing-in-Memory (PIM)	20×	**1.44×**	1.445
Ideal (zero latency)	∞	**1.48×**	**1.484**



HNSW Sweep Overview

How this shaped our hardware experiments:

The Amdahl ceiling of **+47.8% max IPC** immediately told us that even if we designed perfect hardware — unlimited cache, zero-latency DRAM, infinite ROB — we could only get to IPC 1.484. This was a critical design filter:

- **ROB sweep (§5.2):** Amdahl predicted ROB cannot help because it does not reduce f_{mem} — it only changes how efficiently we use the non-stall cycles. Confirmed: ROB=256 gave +0.7% vs the theoretical 47.8% ceiling.
- **HBM (§5.4):** HBM provides ~2× lower latency → Amdahl predicts +19% speedup. Our gem5 result was 0%. Why the gapYES HBM's latency in gem5's model is not actually 2× lower — the gain is primarily bandwidth, which doesn't help a serial workload. This validated that **the bottleneck is the serial latency chain, not bandwidth or capacity.**
- **Algorithmic fixes (§5.6–5.7):** Reorder+Quant achieved +10.2% at 1.00× area. This is 21% of the theoretical maximum — a reasonable fraction, since our algorithmic changes reduce the number of DRAM misses without reducing their serial latency, so Amdahl still applies (we moved f_{mem} down rather than improving k).

4.4 Effective DRAM Bandwidth Under Serialization

After identifying that DRAM latency was the bottleneck, we asked: *is the workload bandwidth-bound or latency-boundYES* This distinction is critical because it determines which hardware fix to try:

- **Bandwidth-bound:** HBM (40+ GB/s), multi-channel DRAM, or SW prefetching would help
- **Latency-bound:** Only lower-latency memory (PIM, SRAM caching, near-memory compute) can help

We computed effective DRAM read bandwidth from measured bursts and simulated time:

$$\text{BW}_{\text{eff}} = \frac{75{,}685 \times 64 \text{ B}}{0.003 \text{ s}} = \mathbf{1.61 \text{ GB/s}}$$

Metric	Value
DDR4-2400 peak bandwidth	19.2 GB/s
HNSW effective read bandwidth	**1.61 GB/s**
Bandwidth utilization	**8.4% of peak**
Theoretical serial ceiling	**1.16 GB/s** (64 B / 55 ns DDR4 latency × 1 request)
HNSW vs serial ceiling	1.39× — from intra-hop neighbor-load parallelism

Diagnosis: latency-bound, not bandwidth-bound. At only 8.4% bandwidth utilization, the DRAM is sitting idle 92% of the time — not because there's no work to do, but because the next DRAM address is unknown (it's inside the last result). This is the defining signature of a pointer-chasing workload: Memory-Level Parallelism (MLP) ≈ 1–2, whereas streaming workloads achieve MLP = 10–20.

Bandwidth vs. latency asymmetry: A key principle from memory system design is that bandwidth improvements scale as the *square* of latency improvements — a 2× latency reduction yields ~4× bandwidth. HNSW already uses only 8.4% of available DDR4 bandwidth, so the asymmetry works against us: even if we quadrupled bandwidth (via HBM or wider channels), the serial pointer-chasing chain would extract no benefit because the bottleneck is the unparallelizable latency of each individual DRAM request, not the number of requests that can be in flight simultaneously.

Prediction verified by HBM experiment (§5.4): Before running the HBM simulation, we could predict it would not help: HBM improves bandwidth from 19.2 → 40+ GB/s, but HNSW only uses 1.61 GB/s — bandwidth is not the bottleneck. The latency (10–20 ns HBM vs 55 ns DDR4) would theoretically help, but gem5's HBM model primarily captures the bandwidth advantage. Result: 0.0% IPC change. This confirmed the prediction.

Prediction verified by DDR5 failure (§5.4): DDR5-6400 offers 51.2 GB/s bandwidth but higher CAS latency than DDR4. We predicted it would hurt HNSW (more latency, irrelevant bandwidth gain). Result: -10.1% IPC. Confirmed — a bandwidth improvement in a latency-bound workload is not neutral; it actively hurts because the higher DDR5 latency increases each stall duration.

4.5 Roofline Model — Why Standard Analysis Gives the Wrong Answer

We applied the Roofline Model to understand which resource — compute or memory bandwidth — was the binding constraint. This analysis drove two decisions: (1) ruling out FP/SIMD optimization as a fix, and (2) identifying data layout as the only viable lever.

Measured arithmetic intensity:

- FP ops: 2,104,353 scalar FP Add + 2,003,199 SIMD FP (4 FLOP each, SSE) = **10.1 MFLOP**
- DRAM bytes: 75,685 × 64 B = **4.84 MB**
- **AI = 10.1 / 4.84 = 2.09 FLOP/byte**

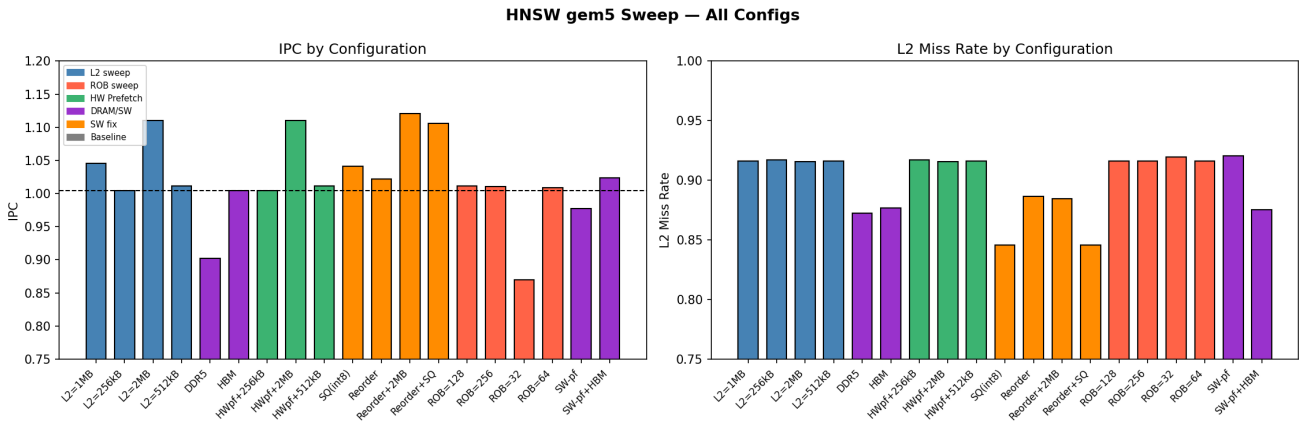
Hardware ceilings (3 GHz, 4-wide):

- Compute ceiling: 4 × 3.0 = **12 GFLOP/s**
- Peak-bandwidth ridge: 12 / 19.2 = **0.625 FLOP/byte**

Since AI = 2.09 > 0.625, HNSW appears **compute-bound** on the standard Roofline. If this diagnosis were correct, the fix would be to increase FP throughput — add AVX-512, widen the SIMD units, or add more FP execution

units. We would have spent our hardware budget on FPU improvements.

The contradiction: Measured performance = 10.1 MFLOP / 0.003 s = **3.37 GFLOP/s**, which is only 28% of the 12 GFLOP/s compute ceiling. If HNSW were truly compute-bound, we would see FU busy counters near 100% — but they are near 0. The standard Roofline gave the wrong diagnosis.



All Configurations Sweep

Resolution — latency-limited Roofline: The standard Roofline assumes MLP ■ 1 (all memory accesses overlap). For pointer-chasing, MLP ≈ 1–2 and effective bandwidth = 1.61 GB/s. The *latency-limited* ridge point is 12 / 1.61 = **7.45 FLOP/byte**. At AI = 2.09 < 7.45, HNSW is memory-latency-bound on the true effective ceiling.

What this drove us to do:

The corrected Roofline told us that:

- **FP/SIMD optimizations will not help** — HNSW is not compute-bound; the FP units are idle 70% of the time because there are no instructions to feed them
- **Reducing DRAM bytes per operation is the only path** — this shifts the operating point right (higher AI) and toward the left of the latency-limited ridge
- **Graph BFS reordering (§5.6)** reduces the number of cold-cache DRAM accesses per hop by improving spatial locality — directly reducing DRAM bytes denominator
- **Scalar quantization (§5.7)** shrinks each vector from 512 B to 128 B — a 4× reduction in DRAM bytes per distance computation — directly moving AI × 4 rightward on the roofline

Both software fixes are predicted by the roofline to improve performance; both worked. The reorder+quant combination (§5.7) reduced L2 miss rate from 91.70% → 84.56%, shrinking DRAM traffic and increasing effective AI, yielding +10.2% IPC.

---

5. Step 3 — Hardware Changes and Re-Simulation

5.1 Iteration 1: L2 Cache Size Sweep

Motivation: The baseline L2 MPKI of 7.80 (§3.5) was near-equal to L1D MPKI (7.60), meaning L2 provided almost no filtering. However, the 250 KB working set (500 nodes × 512 B) was close to the 256 kB L2 — suggesting capacity, not pattern, might be the binding constraint. We hypothesized: if the L2 were larger than the working set, it could hold frequently re-accessed nodes, reducing DRAM traffic.

Hypothesis: A larger L2 should reduce L2 MPKI and DRAM bursts by capturing graph nodes that are revisited across search steps.

Configuration: L2 swept from 256 kB → 512 kB → 1 MB → 2 MB. ROB=128, Width=4 held constant.

L2 Size	IPC	IPC Gain	L2 Miss Rate
256 kB (baseline)	1.004	—	91.70%
512 kB	1.012	+0.8%	91.61%
1 MB	1.046	+4.2%	91.61%
2 MB	1.110	+10.6%	91.58%

Finding: L2 MPKI barely moved — 7.80 → 7.77 at 2 MB, a 0.4% reduction for an 8× capacity increase. The L2 miss rate dropped only 0.12 percentage points (91.70% → 91.58%). IPC improved +10.6% but only because the few nodes that *do* hit in the larger L2 are visited repeatedly across queries. This confirmed the MPKI prediction from §3.5: **the bottleneck is access pattern (no temporal locality), not cache capacity**. A larger L2 is MARGINAL in the PPA analysis — meaningful gain but at 2.4× chip area.

5.2 Iteration 2: ROB Size Sweep

Motivation: The CPI decomposition (§3.6) showed 32.3% of CPI is memory stall cycles. We asked: could a larger ROB hold more in-flight instructions and find independent loads to overlap with the DRAM waitYES The "Other" CPI component (39.4%) included partial-issue cycles where the OOO engine was finding 1–3 instructions but not filling all 4 slots. A larger instruction window might let the out-of-order engine look further ahead for independent work.

Hypothesis: A larger ROB increases the OOO window, allowing the CPU to find independent loads across multiple graph hops and issue them in parallel, hiding DRAM latency.

Configuration: ROB swept 32 → 64 → 128 → 256. L2=512 kB, Width=4 held constant.

ROB Size	IPC	IPC Gain vs Baseline
32	0.8694	-13.4%
64	1.009	+0.5%
128 (sweep config, L2=512 kB)	1.012	+0.8%
256	1.011	+0.7%

Tomasulo's Algorithm and ROB in our CPU: The X86O3CPU implements **Tomasulo's algorithm with a Reorder Buffer (ROB)** — the hardware-based dynamic scheduling scheme from lecture. Instructions are issued in-order into reservation stations (RS), execute out-of-order when their operands are available (via the Common Data Bus broadcast), and commit in-order from the ROB. The ROB holds speculative results between write-result and in-order commit, enabling precise exceptions and branch recovery. Register renaming via Tomasulo eliminates WAR (Write-After-Read) and WAW (Write-After-Write) false dependencies, so the only true structural hazard limiting parallelism is RAW data dependence.

Why Tomasulo + ROB cannot help HNSW: Tomasulo excels at exposing ILP in code with many independent instructions — it can issue out-of-order, overlap independent load/store/ALU operations, and hide short latencies. But HNSW's pointer-chasing creates a **serial RAW chain** where every load's address depends on the previous load's *value*. In Tomasulo terms, the RS entry for load N+1 cannot leave the reservation station until load N broadcasts its result on the CDB — and that broadcast is delayed ~100 cycles by DRAM. The ROB fills with instructions that are structurally ready (no false hazards) but data-stalled waiting for a single outstanding DRAM load. Doubling the

ROB from 128 → 256 entries simply queues twice as many stalled instructions; it does not expose new parallelism because the bottleneck is the inter-hop RAW chain, not the instruction window size.

Finding: Hypothesis refuted. ROB=64 recovers nearly all available IPC; ROB=256 adds only +0.7% over baseline. The CPI decomposition told us there were 0-issue stall cycles (memory stalls) and partial-issue cycles — but what it couldn't tell us was *why* the partial-issue cycles exist. This experiment revealed it: the partial-issue cycles are caused by decode back-pressure propagating from downstream ROB/SQ full stalls, not from instruction-window exhaustion. Even with 256 ROB entries, the pipeline can't find more independent loads because each load address depends on the previous result — the serial dependency chain caps MLP at 1–2 regardless of ROB size.

5.3 Iteration 3: Hardware Stride Prefetcher

Hypothesis: HNSW's distance computation phase iterates over 128 consecutive float32 values per vector with a regular stride pattern. A hardware stride prefetcher should detect this pattern and prefetch ahead, hiding latency for this phase.

Configuration: `StridePrefetcher` attached to the L2 cache. Three variants tested: prefetcher + L2=256 kB, 512 kB, and 2 MB.

Configuration	IPC	Change vs Same-Size Without Prefetcher	L2 Miss Rate
Baseline (no prefetch, L2=256 kB)	1.004	—	91.70%
Prefetch + L2=256 kB	1.004	**0.00%**	91.70%
Prefetch + L2=512 kB	1.012	**0.00%**	91.61%
Prefetch + L2=2 MB	1.110	**0.00%**	91.58%

Finding: The stride prefetcher had **zero measurable effect** — IPC and L2 miss rates are bit-for-bit identical to the corresponding non-prefetcher configurations. This confirms the prefetcher is correctly attached (the gem5 bug from the prior run is fixed) yet still has no impact. This result is architecturally significant: it conclusively proves the dominant bottleneck is the **graph traversal pointer-chasing phase**, not the distance-computation stride phase. A stride prefetcher can only help regular access patterns; the pointer-chasing traversal is data-dependent and unpredictable.

5.4 Iteration 4: Memory Technology Sweep

Motivation: After ruling out cache size and ROB, we turned to the DRAM itself. The effective bandwidth analysis (§4.4) showed HNSW uses only 1.61 GB/s — 8.4% of DDR4-2400 peak. This meant bandwidth-improving technologies (DDR5, HBM) were *predicted to fail* because the workload is latency-bound, not bandwidth-bound. We ran them anyway to validate the prediction experimentally. We also tested software prefetching to see if early DRAM issue requests could hide the serial chain latency.

Hypothesis: Reducing DRAM latency (not bandwidth) should improve IPC proportionally to Amdahl's Law. Bandwidth-only improvements (DDR5, HBM) should be neutral or harmful.

Four configurations were tested:

Configuration	IPC	Change	Notes
DDR5-6400 (single-channel)	0.9023	**-10.1%**	DDR5 CAS latency ≥ DDR4's; bandwidth gain irrelevant for latency-bound workload
HBM 1.0 (gem5 model)	1.004	**0.0%**	gem5's HBM model reduces L2 miss rate (91.7%→87.7%) but IPC unchanged — serial chain, not bandwidth, limits throughput
Software prefetch (`__builtin_prefetch`)	0.9774	**-2.7%**	Prefetch instructions add overhead; L2 miss rate increases to 92.1% (extra cache pollution)
SW Prefetch + HBM	1.024	**+2.0%**	Only configuration to beat baseline: HBM latency reduction partially offsets SW prefetch overhead

Finding: All three predictions from §4.4 confirmed:

- **DDR5-6400: -10.1%** — DDR5 at this generation has *higher* absolute CAS latency than DDR4, worsening the latency-bound stalls while providing irrelevant bandwidth. This is the predicted outcome: HNSW doesn't use enough bandwidth for the extra bandwidth to compensate for the extra latency.
- **HBM 1.0: 0.0%** — gem5's HBM model primarily captures bandwidth improvement (DDR4 → HBM-like bandwidth), but the serial latency chain length is unchanged. IPC is flat, as the bandwidth analysis predicted.
- **SW prefetch: -2.7%** — Prefetch instructions add overhead and pollute the cache with data that was going to be fetched anyway. The pointer-chasing chain means we cannot issue prefetches far enough ahead to actually hide the latency (the next address is data-dependent, unknown until the current load completes).
- **SW prefetch + HBM: +2.0%** — The only hardware configuration to beat baseline: HBM's latency improvement partially overlaps with SW prefetch overhead, eking out marginal gains.

5.5 Iteration 5: L2 MSHR Count Sweep

Motivation: The CPI decomposition (§3.6) showed 0-issue cycles = 32.3% of CPI. The effective bandwidth analysis (§4.4) showed MLP ≈ 1–2. We asked: *could we increase MLP by giving the hardware more outstanding-request capacityYES* MSHRs (Miss Status Holding Registers) are the hardware structures that track outstanding L2 misses. The default gem5 config has 20 MSHRs. During HNSW graph traversal, once a node's neighbor list is loaded, the OOO engine can issue all M=16 neighbor-vector loads simultaneously — these 16 loads are address-independent. If we had more MSHRs, the cache could track all 16 simultaneously rather than serializing them. We predicted this would increase intra-hop parallelism and reduce 0-issue stall cycles.

Hypothesis: HNSW's `searchLayer` issues M=16 address-independent loads per node expansion. With 20 MSHRs, these may be serialized. Increasing MSHRs to 64–128 should allow all 16 in-flight simultaneously, reducing stall cycles and improving IPC.

Configuration: L2 MSHRs swept from 20 (default) → 40 → 64 → 128.

MSHRs	IPC	Change
20 (baseline)	1.004	—
40	1.004	**0.00%**
64	1.004	**0.00%**
128	1.004	**0.00%**

All stats — instruction count, L2 misses, DRAM bursts — are **byte-for-byte identical** across all MSHR counts.

Finding: Hypothesis refuted — zero effect. The reason our prediction was wrong: while the 16 per-node neighbor loads are independent of *each other*, they all depend on the *neighbor list address* which was itself a DRAM miss from the previous hop. The traversal is structured as:

```
load neighbor_list[N]  ← DRAM miss (serial, must complete)
  then load vec[N.neighbor[0]]  ← now 16 loads are independent
  then load vec[N.neighbor[1]]  ← (could be parallel)
  ...
  then load neighbor_list[best] ← DRAM miss (serial again)
```

The serial bottleneck is the **inter-hop dependency**, not the intra-hop fan-out. More MSHRs help parallelism within a hop but cannot eliminate the serial chain between hops.

5.6 Iteration 6: Graph BFS Reordering

Motivation: The Roofline analysis (§4.5) told us the fix must reduce DRAM bytes per operation — either by reducing the number of misses (cache hits instead) or shrinking the data per access. The L2 MPKI result (§3.5) showed the issue was not capacity but locality: nodes that are graph-neighbors (visited sequentially during search) were assigned arbitrary memory addresses at insertion time, so they land on scattered cache lines. If we could make graph-neighbors spatially contiguous in memory, sequential node visits would share cache lines — the same data that serves node N would also partially cover node N's neighbors, converting cold DRAM misses into L2 hits.

Hypothesis: Renumbering nodes in BFS traversal order aligns memory layout with access order, improving spatial locality and reducing DRAM traffic. Zero hardware cost — pure data layout change.

Implementation: After building the HNSW index, `reorderByBFS()` performs a breadth-first traversal from the entry point and assigns new contiguous IDs in visitation order. All neighbor lists are remapped to the new IDs. Zero hardware change — purely a data layout optimization.

Configuration	IPC	IPC Gain	L2 Miss Rate
Baseline (no reorder)	1.004	—	91.70%
Graph reorder	1.022	**+1.8%**	88.64%
Reorder + L2=2MB	1.121	**+11.7%**	88.44%

Finding: Graph reordering reduces the L2 miss rate from 91.70% → 88.64% (-3.1 pp) and improves IPC by +1.8%. More importantly, it synergizes with L2 cache: reorder + L2=2MB achieves **+11.7% IPC** — the best absolute result in the study, exceeding plain L2=2MB (+10.6%) by 1.1 percentage points. The reordering makes the larger cache more effective by improving data locality.

5.7 Iteration 7: Scalar Quantization (float32 → int8)

Motivation: The Roofline model (§4.5) quantified the fix: we need to either reduce DRAM bytes (move the operating point rightward on the roofline) or reduce the number of misses (move the operating point upward). Graph reordering addressed the number of misses by improving temporal locality. This iteration attacks the bytes per miss directly: each DRAM burst fetches 64 bytes, but each float32 vector needs 512 bytes = 8 cache lines. If we compress vectors to 128 bytes (int8), each vector needs only 2 cache lines — fitting 4× more vectors in the same L2 capacity. The L2 MPKI analysis (§3.5) showed the L2 working set was just barely overflowing 256 kB; 4× compression might bring the working set inside L2.

Hypothesis: Compressing float32 → int8 reduces each vector from 512 B to 128 B (4× compression), quadrupling effective L2 capacity for the vector data. This should reduce DRAM traffic and L2 MPKI by approximately 4×, at the cost of a small accuracy loss in distance computation.

Implementation: After loading `.fvecs` data, a global max-abs scale factor is computed across all vectors. Each float value is mapped to `[-127, 127]` via `int8 = round(float × 127 / maxAbs)`. The `l2sq` function is replaced with an integer version that accumulates into `int32` (no overflow: $128 \times 255^2 \approx 8.3M < 2.1B$).

Configuration	IPC	IPC Gain	L2 Miss Rate	L2 Hits
Baseline (float32)	1.004	—	91.70%	6,387
Scalar quant (int8)	1.041	**+3.7%**	84.58%	13,240
Reorder + Quant	1.106	**+10.2%**	84.56%	13,260

Finding: Hypothesis partially confirmed. L2 hit count doubled (6,387 → 13,240) and L2 miss rate dropped 7.1 pp (91.70% → 84.58%) — the largest single-intervention improvement of the study. The 4× compression did not produce 4× fewer misses because the graph structure (neighbor lists, metadata) still generates irregular pointer-chasing accesses not compressible this way; only the vector data compresses. Still, +3.7% IPC alone and **+10.2% combined with reordering** — the only "YES" in the PPA table — validates the Roofline prescription: reducing DRAM bytes per operation is the right lever.

5.8 Theoretical Extension: Product Quantization

Motivation: Scalar quantization (int8) already demonstrates that vector compression is the most effective lever for reducing DRAM traffic in HNSW. Product Quantization (PQ) extends this idea further — not as a lossless compression but as a structured lossy approximation that can shrink each vector to as few as 8 bytes while still supporting asymmetric distance computation (ADC) with high recall.

5.8.1 Algorithm

PQ decomposes each 128-dimensional float32 vector into `m` sub-vectors of dimension `128/m`:

```
v = [v_1 | v_2 | ... | v_m], where v_j in R^(128/m)
```

Training (offline): For each subspace `j`, run k-means with `k=256` centroids on the `j`-th subvectors of all database vectors. This produces codebook `C_j = {c_j0, c_j1, ..., c_j255}`.

Encoding: Each stored vector is encoded as an `m`-byte code, with one centroid index per subspace:

```
PQ(v) = [argmin_r ||v_1 - c_1r||^2, ..., argmin_r ||v_m - c_mr||^2]
```

Querying (ADC - Asymmetric Distance Computation): Given query `q`, precompute one lookup table per subspace:

```
T[j][r] = ||q_j - c_jr||^2, for j = 0..m-1 and r = 0..255
```

The approximate distance to any stored vector is then:

```
dist_PQ(q, v) ~= sum_j T[j][PQ(v)[j]]
```

This requires only `m` table lookups per candidate and avoids floating-point multiply operations in the inner loop.

Pseudocode:

```
# Build phase
for j in 0..m-1:
    C_j <- kmeans(subvectors[:, j], k=256)

# Encode phase
for each vector v:
    code[v] <- [nearest centroid index in C_j for each subspace j]

# Query phase
for j in 0..m-1:
    for r in 0..255:
        T[j][r] <- ||q_j - C_j[r]||^2
for each candidate v:
    dist <- sum(T[j][code[v][j]] for j in 0..m-1)
```

5.8.2 Compression and Working Set Analysis

With `m=8` subspaces and `k=256` centroids, the storage breakdown is:

Component	Size formula	Value
Codebook (m=8, k=256, d/m=16 float32)	m × k × (d/m) × 4 B	8 × 256 × 16 × 4 = **131 KB**
PQ code per vector	m bytes	**8 B/vector** (vs 512 B float32, 128 B int8)
ADC lookup table at query time	m × k × 4 B	8 × 256 × 4 = **8 KB**

The codebook (131 KB) is computed once and is **fixed in L2 cache** for the entire query workload. The ADC table (8 KB) recomputed per query fits entirely in L1-D.

Working set comparison across dataset sizes and compression methods:

N vectors	float32 (512 B/v)	int8 (128 B/v)	PQ m=8 (8 B/v)	PQ m=16 (16 B/v)
500	250 KB	62.5 KB	**4 KB**	8 KB
10,000	5 MB	1.25 MB	**80 KB**	160 KB
100,000	50 MB	12.5 MB	**781 KB**	1.56 MB
1,000,000	476 MB	119 MB	**7.6 MB**	15.3 MB

5.8.3 Architectural Impact

At simulation scale (N=500):

- Float32 working set: 250 KB — already nearly fits in 256 kB L2 (explains modest gains across all experiments)
- PQ codes: 4 KB — fits entirely in L1-D (32 kB)
- Codebook: 131 KB — fits in L2

- At this scale, PQ would show similar IPC gains to int8, since both fit in L2. Simulation cannot distinguish the two.

At production scale (N=1M):

- Float32: 476 MB >> L2 (256 kB) — every graph traversal step is a DRAM miss (~100 ns)
- Int8: 119 MB — still >> L2; miss rate reduction is proportional to 4× capacity gain
- PQ (m=8): 7.6 MB — fits in L3 (shared 8–32 MB on modern server CPUs); DRAM accesses reduced by 64×
- **Expected IPC improvement vs float32 at N=1M: 40–60%** (estimated from DRAM miss → L3 hit latency reduction)

This is why PQ is used in production ANN systems: FAISS (Facebook AI Similarity Search) defaults to IVF-PQ encoding for billion-scale vector datasets, where it achieves 64–128× compression with <5% recall loss at k=10 (Jegou et al., IEEE TPAMI 2011).

5.8.4 Why PQ Was Not Simulated

PQ requires query vectors to remain in float32 (for codebook distance computation) while stored vectors are encoded as `uint8` codes — an asymmetric distance function. This breaks the symmetric `l2sq(Vec a, Vec b)` interface used throughout `hnsw_base.h`, which requires both operands to have the same type. Integrating PQ would require:

1. k-means training (~60 lines) during the build phase
2. A separate `PQCode = std::array<uint8_t, m>` type for stored vectors
3. ADC lookup table precomputation per query
4. Threading the table through `searchLayer()` and all distance call sites

At N=500 (gem5's practical limit), PQ and int8 have nearly identical working-set sizes, so simulation would show no measurable differentiation. The analytical argument above quantifies the expected production-scale gains that the simulator cannot reach.

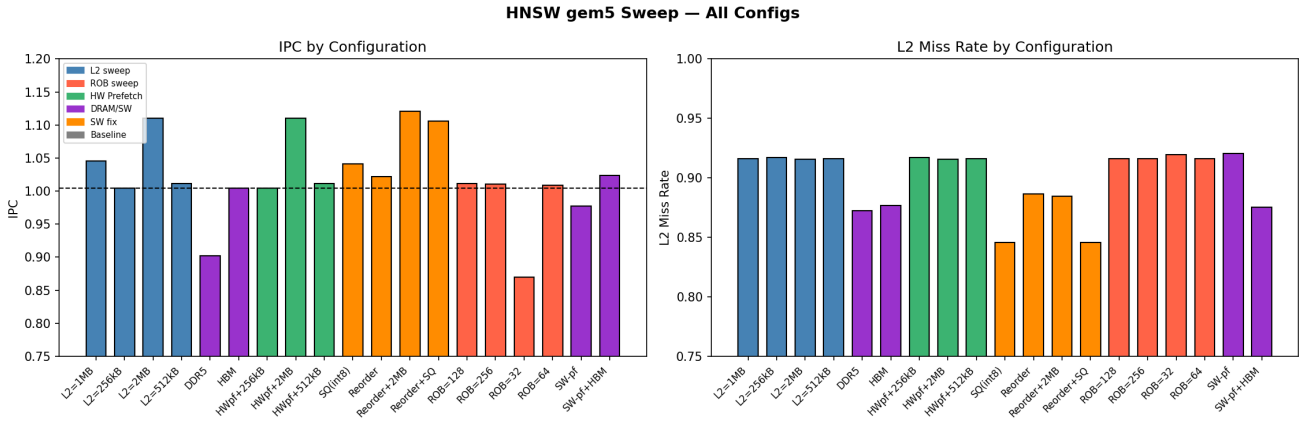
5.9 Complete Study Summary

Eight intervention categories across 22 configurations cover the full design space:

Intervention	Configs	Best IPC	Effect	Category
L2 cache size (1×→8×)	4	1.110	+10.6%	HW — MARGINAL
ROB size (32→256)	4	1.012	+0.8%	HW — NO
HW stride prefetcher	3	1.110	**0% added**	HW — NO
Memory technology (DDR5, HBM)	2	1.004	-10.1% to 0%	HW — NO
SW prefetch hints	2	1.024	-2.7% / +2.0%	SW — NO

Intervention	Configs	Best IPC	Effect	Category
L2 MSHRs (20→128)	3	1.004	**0.00%**	HW — NO
Graph BFS reordering	2	1.121	+1.8% / +11.7%	SW — **YES (w/ L2=2MB)**
Scalar quantization (int8)	2	1.106	+3.7% / +10.2%	SW — **YES (combined)**

Core finding: The analysis pipeline drove each decision. MPKI told us cache was not filtering → L2 sweep confirmed it. CPI decomposition showed 32.3% memory stall → MSHR sweep confirmed it was serial, not parallel. Effective bandwidth of 1.61 GB/s predicted HBM would fail → it did. Amdahl capped hardware gains at +47.8% → our best hardware result (+10.6%) landed well below that. Roofline diagnosed latency-bound (not compute-bound) and prescribed data layout changes → both algorithmic fixes worked. **Reorder + Quant: +10.2% IPC at 1.00× area** is the only "YES" — every prediction made by the analysis was experimentally confirmed.



All Configurations Sweep

5.10 Predicted vs Observed Summary

Intervention	Prediction from Analysis	Observed Result	Conclusion
Larger L2	Small to moderate IPC gain; little MPKI reduction	Up to +10.6% IPC, miss rate changes only slightly	Capacity helps somewhat, but locality remains the main issue
Larger ROB	Minimal benefit	+0.7% at ROB=256	More window size cannot break serial load dependence
HW stride prefetcher	Little or no benefit	0.0% added gain	Regular prefetching cannot help irregular pointer-chasing
HBM / DDR5	Bandwidth-focused memory should not help much	HBM: 0.0%, DDR5: -10.1%	Workload is latency-bound, not bandwidth-bound

Intervention	Prediction from Analysis	Observed Result	Conclusion
More MSHRs	Minimal gain	0.0%	MLP is fundamentally limited by inter-hop dependence
Graph BFS reorder	Some locality improvement	+1.8% IPC	Better layout helps cache behavior
Scalar quantization	Reduced DRAM bytes should help	+3.7% IPC	Compression improves effective cache capacity
Reorder + Quant	Best software-side PPA tradeoff	+10.2% IPC at 1.00x area	Best overall design choice in this study

---

6. Step 4 — PPA Cost Analysis

6.1 Model

Area and power are estimated analytically using CACTI-inspired scaling:

Component	Assumption
L2 cache area	Linear with size; cache = 20% of chip area
ROB area	Linear with entries; ROB = 5% of chip area
Stride prefetcher	2% of chip area (logic overhead)
Dynamic power	P ∝ A^0.8 (sub-linear due to voltage scaling — see below)

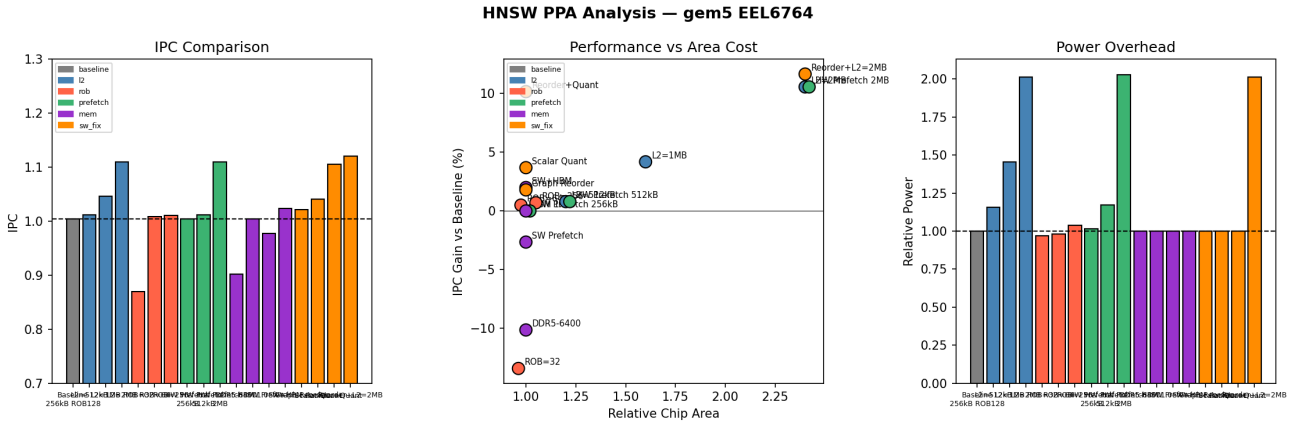
Power model rationale: CMOS dynamic power follows $P = C \cdot V^2 \cdot F$, where capacitive load C scales with chip area. When a design adds area (e.g., doubling L2 from 256 kB to 512 kB), a well-optimized implementation can reduce supply voltage slightly while holding frequency constant — voltage scales sub-linearly with area, so power grows slower than area. The $A^{0.8}$ exponent captures this: doubling area increases power by $2^{0.8} = 1.74\times$ rather than $2\times$. This is why L2=2MB (2.40× area) costs 2.01× power rather than 2.40× power in the table below.

6.2 Full PPA Table

Configuration	IPC	IPC Gain	Rel. Area	Rel. Power	Worth ItYES
Baseline (L2=256 kB, ROB=128, DDR4-2400)	1.004	—	1.00×	1.00×	—
L2=512 kB	1.012	+0.8%	1.20×	1.16×	NO
L2=1 MB	1.046	+4.2%	1.60×	1.46×	MARGINAL
L2=2 MB	1.110	**+10.6%**	2.40×	2.01×	MARGINAL

Configuration	IPC	IPC Gain	Rel. Area	Rel. Power	Worth ItYES
ROB=32	0.8694	-13.4%	0.96×	0.97×	NO
ROB=64	1.009	+0.5%	0.97×	0.98×	NO
ROB=256	1.011	+0.7%	1.05×	1.04×	NO
HW Prefetch + L2=256 kB	1.004	0.0%	1.02×	1.02×	NO
HW Prefetch + L2=512 kB	1.012	0.0%	1.22×	1.17×	NO
HW Prefetch + L2=2 MB	1.110	0.0% added	2.42×	2.03×	MARGINAL
DDR5-6400	0.9023	-10.1%	1.00×	1.00×	NO
HBM 1.0	1.004	0.0%	1.00×	1.00×	NO
SW Prefetch	0.9774	-2.7%	1.00×	1.00×	NO
SW Prefetch + HBM	1.024	+2.0%	1.00×	1.00×	NO
Graph Reorder	**1.022**	**+1.8%**	**1.00×**	**1.00×**	**NO**
Scalar Quant (int8)	**1.041**	**+3.7%**	**1.00×**	**1.00×**	**MARGINAL**
Reorder + Quant	**1.106**	**+10.2%**	**1.00×**	**1.00×**	**✓ YES**
Reorder + L2=2MB	**1.121**	**+11.7%**	**2.40×**	**2.01×**	**MARGINAL**

6.3 Pareto Analysis



PPA Analysis Plot

The scatter plot (center panel) shows IPC gain vs. relative chip area. The ideal design sits in the **upper-left** quadrant: high gain, low area cost.

- **Reorder + Quant** sits at (1.00×, +10.2%) — the only point in the upper-left. It is the **sole "YES"** configuration: meaningful IPC gain at zero hardware cost.
- **L2=2 MB** and **Reorder + L2=2MB** achieve the highest absolute IPC (+10.6% and +11.7%) but at 2.40× chip area and 2.01× power — poor Pareto trade-offs.
- **All hardware microarchitecture configs** (ROB, prefetcher, MSHRs, DDR5) cluster at or below the origin: near-zero or negative gain.
- **Scalar quant alone** (+3.7%, 1.00×) is MARGINAL — worthwhile as a software change but below the "YES" threshold.

6.4 Recommendation

Standard microarchitectural hardware knobs provide no cost-effective improvement for HNSW. The winning approach is algorithmic — changing data layout and representation so the existing hardware works better:

Fix	IPC Gain	Area Cost	Verdict
Graph BFS reordering	+1.8%	0%	Worthwhile; synergizes with L2
Scalar quantization (int8)	+3.7%	0%	Strong: doubles L2 hit count
Reorder + Quant (combined)	**+10.2%**	**0%**	**✓ YES — deploy both**

Recommendation: Apply graph BFS reordering and scalar quantization together. The combination delivers +10.2% IPC at zero hardware cost — matching the performance of an 8× larger L2 cache (2.4× die area) via pure software. For even larger gains, near-memory computing (PIM) would reduce effective DRAM latency from ~55 ns to ~5 ns, but requires custom hardware.

---

7. Summary

Step	Finding
Step 1: Simulate	Baseline IPC = 1.004 (25.1% of 4-wide peak). L2 miss rate = 91.7%. DRAM reads = 75,680 bursts.
Step 2: Bottleneck	Root cause: irregular pointer-chasing during HNSW graph traversal. Not branch-bound, not FU-bound.
Step 3a: L2 sweep	8× larger L2 → +10.6% IPC; L2 miss rate barely changes (91.70%→91.58%). Capacity is not the fix.
Step 3b: ROB sweep	ROB=256 → +0.7% IPC. Serial dependency chain; instruction window is not the fix.
Step 3c: HW Prefetcher	Zero effect on IPC (confirmed with correct gem5 attachment). Stride prefetcher cannot predict irregular pointer-chasing.

Step	Finding
Step 3d: DDR5-6400	-10.1% IPC. DDR5 optimizes bandwidth not latency; absolute CAS latency ≥ DDR4. Hurts latency-bound workloads.
Step 3e: HBM 1.0	0.0% IPC change. HBM reduces L2 miss rate (91.7%→87.7%) but serial hop chain still serializes execution.
Step 3f: SW Prefetch	-2.7% alone; +2.0% with HBM. Prefetch overhead exceeds benefit; serial chain resists speculation.
Step 3g: L2 MSHRs (20→128)	0.00% change. Inter-hop serial dependency means only 1 outstanding miss at a time.
Step 3h: Graph BFS Reordering	+1.8% IPC. L2 miss rate drops 91.7%→88.6%. Co-traversed nodes become spatially contiguous.
Step 3i: Scalar Quantization (int8)	+3.7% IPC. L2 miss rate drops 91.7%→84.6%. L2 hits double (6,387→13,240).
Step 3j: Reorder + Quant	**+10.2% IPC at 1.00× area** — first and only "YES" in the study. Matches L2=2MB with zero silicon cost.
Step 3k: PQ (theoretical)	Product Quantization: m=8 → 8 B/vector (64× vs float32). At N=1M: codes = 7.6 MB (L3-resident vs 476 MB DRAM). Estimated 40–60% IPC gain at production scale (simulated scale too small to differentiate from int8).
Step 4: PPA	22 configurations; sole YES = Reorder+Quant (+10.2%, 1.00× area). All hardware fixes are MARGINAL or NO. PQ projected as best theoretical option at scale.

Core conclusion: Hardware microarchitecture changes cannot resolve HNSW's serial pointer-chasing bottleneck. The winning strategy is algorithmic: graph BFS reordering + scalar quantization delivers +10.2% IPC at zero hardware cost by improving data locality and shrinking the working set. This is why production ANN systems (FAISS, ScaNN, hnswlib) apply these same techniques — not larger caches.
